## Abstract

Bio-geo-chemical models are useful tools in environmental sciences that can guide management and policy-making. Consequently, significant time and resources are spent developing these models in system-specific contexts. The optimization of model parameters to maximize precision, including transferability of these models to different systems, are fundamental concerns in the development and application of these tools. This study provides a context for understanding quantitative limitations of coupled hydrodynamic-ecological models by evaluating parameter sensitivity and identifiability of a <sup>acro:zerod</sup> zero-dimensional (0-D) unit of a larger spatio-temporal model of hypoxia on the Louisiana continental shelf of Gulf of Mexico. The analysis provides a contrast of numeric and ecological certainty in parameter subsets using a systematic framework to infer larger trends in dissolved oxygen dynamics over time, having implications for understanding factors that contribute to environmental conditions that are detrimental to aquatic resources. In particular, we focus on issues of parameter identifiability using local sensitivity analyses to provide quantitative descriptions of numerical constraints on model precision. We argue that quantitative and ecological certainty in model calibration are often at odds and practitioners must choose explicit model components to optimize given tradeoffs between the two. We further conclude that numerically optimal parameter sets for models of hypoxia are often small subsets of the complete parameter set because of redundancies in the unique effects of parameter perturbations on model output. As a result, we demonstrate that use of a model for inference into ecological mechanisms of observed or predicted changes in hypoxic condition can be potentially misguided in the absence of quantitative descriptions of identifiability. Although these concerns have been expressed in the literature, they are rarely explicitly addressed or included in model evaluations. In addition to immediate implications for regional models, we provide a framework for describing the effects of parameter uncertainty and identifiability that can be applied to similar models to better inform environmental management.

## 1 Introduction

Hypoxia formation in bottom waters of coastal oceans occurs primarily from excess nutrient inputs from land-based sources (Justić et al. 1987, Diaz and Rosenberg 1995, Howarth et al. 1996). These events are detrimental to aquatic organisms and have significant negative effects on economic resources derived from coastal ecosystems (Lipton and Hicks 2003, Diaz and

Rosenberg 2011). An understanding of the biological, physical, and chemical processes that contribute to the growth of hypoxic areas is a critical concern for mitigating and preventing these negative impacts. Numerical ecosystem models have been important tools for describing current knowledge of ecosystem processes that contribute to hypoxia formation and for predicting the effects of proposed management activities or future scenarios (Scavia et al. 2004, Hagy and Murrell 2007, Pauer et al. 2016). Unlike statistical models that have more generic structures, simulation and process-based models include explicit descriptions of relevant processes that are constrained by empirical or observational data relevant to the system of interest (e.g. Omlin et al. 2001b, Eldridge and Roelke 2010). These models are often coupled with hydrodynamic grids to provide spatially-explicit representations of patterns in three dimensions (Warner et al. 2005, Zhao et al. 2010, Ganju et al. 2016). Combined hydrodynamic and bio-geo-chemical models have been developed specifically to describe hypoxic conditions on the <sup>acro:lcs</sup>Louisiana continental shelf (LCS) in the northern <sup>acro:gom</sup>Gulf of Mexico (GOM) (Fennel et al. 2013, Obenour et al. 2015, Pauer et al. 2016, Lehrter et al. in review). This area drains a significant portion of the continental United States through the <sup>acro:marb</sup>Mississippi-Atchafalaya River Basin (MARB) and is the second largest hypoxic area in the world (Rabalais et al. 2002). Understanding processes that contribute to the frequency and duration of hypoxic events remains a critical research goal for the region, including the application of process-based models to characterize the current knowledge domain.

The development and application of a model represents a tradeoff between characteristics expected from the output or provided by the structural components. An idealized model is sufficiently generalizable across systems, provides results that are precise given the inputs, and includes components that are realistic descriptions of actual processes (Levins 1966). Given that these characteristics cannot be simultaneously achieved, models are developed in partial dependence of reality and theoretical constructs, completely separate from both, or dependent on one or the other (Morrison and Morgan 1999, Ganju et al. 2016). These challenges are analogous to the well-known bias-variance tradeoff in statistical models that balances the competing objectives of over- and under-fitting to an observed dataset. Process-based models are more commonly imbalanced between reality and theory, such that most are over-parameterized in an attempt to completely describe reality (Denman 2003, Nossent and Bauwens 2012, Petrucci and Bonhomme 2014). Such over-parameterization, including use of many structural equations, can

have serious implications for practical applications. Quantitative limitations of over-parameterization are analogous to degrees of freedom in standard statistical models as free parameters cannot be numerically estimated when constrained to an observed dataset (Kirchner 2006). More importantly, over-parameterization can limit use across systems outside of the data domain and impose uncertainty in model predictions as realistic values for every variable may not be known or inaccurately applied from existing studies (Durand et al. 2002, Refsgaard et al. 2007, Wade et al. 2008). The application of process-based models to describe hypoxia dynamics has not been immune to these challenges and comprehensive approaches are needed to develop models that more carefully balance theory with reality (e.g., Snowling and Kramer 2001).

Standard approaches for uncertainty analysis can be used to begin addressing model complexity issues. In the most general sense, uncertainty is evaluated relative to the effects of input conditions or the observed data used to calibrate a model, changes in parameter values, or variation in the structural components (Beck 1987). Evaluating parameter uncertainty is by far the most common and simplest means of evaluating model behavior. Although uncertainty analyses should be integrated throughout model development and application, parameters are more often evaluated post-hoc as a form of ‘damage control’ for further calibration. This approach is sometimes called inverse modelling where results from sensitivity analyses are used to guide calibration or fit of the developed model to observations (Soetaert and Petzoldt 2010, or confronting models with data, *sensu* Hilborn and Mangel 1997). Parameter sensitivity analysis combined with inverse modelling necessarily involves questions of parameter ‘identifiability’, where only a subset of parameters can be numerically constrained to the data as compared to the entire parameter set. Redundancies in parameter effects lead to unidentifiable models where optimal solutions may be empirically impossible (i.e., standard algorithms will not converge) or parameter values may be non-unique leading to the right answer for the wrong reason (Kirchner 2006). The concept of identifiable parameter subsets is not foreign to hypoxia or eutrophication models (Omlin et al. 2001a, Estrada and Diaz 2010, Mateus and Franz 2015), although there is a clear need for greater integration of these concepts in model development (Fasham et al. 2006). Moreover, the inclusion of sensitivity and identifiability analyses in model tuning will require the adoption of selection rules that are context-dependent given the subsets that are possible with large parameter sets (e.g., Wagener et al. 2001a,b).

This study describes a parameter sensitivity analysis to evaluate identifiability of parameter subsets for a bio-geo-chemical model of hypoxia for the northern GOM. We evaluate a simple <sup>acro:zerod</sup> zero-dimensional (0-D) unit of a larger spatial-temporal model to explore relationships between multiple parameter sets and hypoxia dynamics on the LCS. Specifically, we provide empirical results to support the assumption that models are generally over-parameterized and only a finite and smaller subset of the larger parameter set can be optimized for a given research question or dataset. We provide explicit guidance for choosing such subsets of the parameter space given constraints on identifiability as directly related to sensitivity analyses. The objectives are to 1) identify the parameters that have the greatest influence on <sup>acro:do</sup> dissolved oxygen ( $O_2$ ) using local sensitivity analysis, 2) quantify the identifiability of subsets of the total parameter space based on sensitivity, 3) and provide a set of heuristics for choosing parameters based on sensitivity, identifiability, and parameter categories, including extension to other state variables provided by the model. A final analysis evaluates identifiability relative to structural uncertainty to provide an example of extending these methods to more complex uncertainty assessments. The optimum parameter space is defined as the chosen subset that represents the maximum number of identifiable parameters. Here, ‘optimum’ is both a qualitative description based on a research question or management goal and a quantitative objective based on numerical optimization criteria for fitting model output to a calibration dataset. These results can be used to refine existing models or guide application of models to novel contexts, such as downscaling or application to new environments. We conclude with a discussion of the implications for hypoxia formation in coastal regions, including management strategies for nutrient reduction and use of mechanistic models to inform decision-making.

## 2 *Methods*

### 2.1 **Model description**

Hypoxic events, defined as  $<2 \text{ mg L}^{-1}$  of  $O_2$  ( $< 64 \text{ mmol m}^{-3}$ ), occur seasonally in bottom waters in the northern GOM. The LCS receives high nutrient loads from the MARB that drains a significant portion of the continental United States. Nutrient-stimulated primary production in surface waters increases biological oxygen demand in bottom waters as sinking organic matter is decomposed (Bierman et al. 1994, Murrell et al. 2013). The hypoxic area

averages 15,540 km<sup>2</sup> annually (1993-2015) with minimum concentrations observed from late spring to early fall. Seasonal variation is strongly related to carbon and nutrient export from the MARB (Lohrenz et al. 2008, Bianchi et al. 2010), whereas hydrologic variation, currents, and wind patterns can affect vertical salinity gradients that contribute to the formation of hypoxia (Wiseman et al. 1997, Paerl et al. 1998, Obenour et al. 2015).

This study evaluated the core unit of a recently developed hydrodynamic and ecological model that describes horizontal and vertical transport and mixing of state variables relevant for hypoxia in the northern GOM. The <sup>acro:cgem</sup>Coastal General Ecosystem Model (CGEM) includes elements from the Navy Coastal Ocean Model (Martin 2000) that describes hydrodynamics on the LCS and a biogeochemical model with multiple plankton groups, water-column metabolism, and sediment diagenesis (Eldridge and Roelke 2010). The hydrodynamic component of CGEM provides a spatially-explicit description of hypoxia using an orthogonal grid with an approximate horizontal resolution of 1.9 km<sup>2</sup> and twenty equally-spaced vertical sigma layers on the shelf (depth  $\leq$  100 m, with additional hybrid layers at deeper depths). The biogeochemical component includes equations for 36 state variables including six phytoplankton groups (with nitrogen and phosphorus quotas for each), two zooplankton groups, nitrate, ammonium, phosphate, dissolved inorganic carbon, oxygen, silica, and multiple variables for dissolved and particulate organic matter from different sources. Atmospheric and hydrological boundary conditions described in Hodur (1997) and Lehrter et al. (2013) are also included in CGEM.

The core unit of CGEM is FishTank, a 0-D model that implements the biogeochemical equations in Eldridge and Roelke (2010) and does not include any form of physical transport (i.e., advection, mixing, or surface flux) nor sediment diagenesis. Although FishTank was developed for specific application in CGEM, it can easily be applied to other hydrodynamic grids. Accordingly, the sensitivity and identifiability analyses described below focused exclusively on FishTank and are informative for both the LCS gridded model as well as potential applications to different systems. The FishTank model provides estimates for the 36 state variables described above using a 0-D parcel that is uniformly mixed as a closed system. A set of initial conditions is provided on execution of the model that is based on observations of relevant variables obtained from research cruises in the northern GOM during April, June, and September of 2006 (Table 1 in Murrell et al. 2014).

Results from FishTank are based on time-dependent differential equations that describe energy flow between phytoplankton and zooplankton groups as affected by nutrient uptake rates, organic matter inputs and losses, inherent optical properties, and temperature (Penta et al. 2008, Eldridge and Roelke 2010, see appendix in Lehrter et al. in review). A total of 108 equations are estimated at each time step to return a value for each of the 36 state variables described by the model. In addition to the initial conditions, 251 parameter values for each of the equations are also supplied at model execution. These parameters define relationships among fixed effects in the equations and represent ecological properties described by the model that influence hypoxia formation. Values for each of the parameters were based on estimates from the literature, field or laboratory-based measurements, or expert knowledge in absence of the former. As such, a sensitivity analysis of parameter values is warranted given that, for example, literature or field-based estimates may not apply under all scenarios or expert knowledge is not completely certain (Refsgaard et al. 2007).

The sensitivity of O<sub>2</sub> to perturbations of all relevant parameters for the 108 equations was estimated using a five minute timestep of FishTank simulations from January 1<sup>st</sup> to December 31<sup>st</sup>, 2006. Irrelevant parameters were removed for several reasons; parameters were not relevant for the 0-D model (i.e., hydrodynamic parameters), were considered physical constants, or had no effect given initial conditions. Additionally, FishTank includes six phytoplankton and two zooplankton groups to describe complexity in community structure and foodweb dynamics. However, structural equations for each group are identical such that chosen parameter values primarily control differences between the groups, e.g., large-bodied or small-bodied plankton, slow-growing or fast-growing plankton, etc. Initial analyses indicated that parameter sensitivity of dissolved oxygen was identical within the six phytoplankton and zooplankton groups. To remove obvious redundancies in the model, the sensitivity analyses were conducted using only one phytoplankton and one zooplankton group. The final parameter set that was evaluated included 51 parameters that were further grouped into one of six categories based on applicable biogeochemical components of the model: optics ( $n = 4$  parameters), organic matter (12), phytoplankton (22), temperature (2), and zooplankton (11). A full description of the model parameters is available as an appendix in Lehrter et al. in review.

## 2.2 Local sensitivity analysis

The analysis focused on sensitivity of  $O_2$  and other state variables (noted below) in the 0-D FishTank model to identify parameters that may affect spatial and temporal variation of hypoxia in the larger model. A local sensitivity analysis was performed by evaluating the change in  $O_2$  following perturbation of each parameter from its original value. The analyses relied exclusively on concepts used in the FME package developed for the R statistical programming language (Soetaert and Petzoldt 2010, RDCT (R Development Core Team) 2016). Parameters were individually perturbed by 50% of the original values and the model was executed to obtain an estimate  $O_2$  sensitivity. For each perturbation, a sensitivity value  $S$  was estimated for each time step  $i$  given a change for parameter  $j$  as:

$$S_{ij} = \frac{\partial y_i}{\partial \Theta_j} \cdot \frac{w_{\Theta_j}}{w_{y_i}} \quad (1)$$

where the estimate depended on the change in the predicted value for response variable  $y$  divided by the change in the parameter  $\Theta_j$  multiplied by the quotient of scaling factors  $w$  for each. The scaling factors,  $w_{\Theta_j}$  for the parameter  $\Theta_j$  and  $w_{y_i}$  for response variable  $y_i$ , were set as the default value of the unperturbed parameter and the predicted value of  $y_i$  after perturbation (Soetaert and Petzoldt 2010). The scaling ensures the estimates are unitless such that the relative magnitudes allow comparisons of model sensitivity to parameters and state variables that differ in scale. Sensitivity values for all  $j$  parameters were summarized across the time series from  $i = 1$  to  $n$  as  $L1$ :

$$L1 = \sum |S_{ij}|/n \quad (2)$$

All parameters for each of the six equation categories (optics, organic matter, phytoplankton, temperature, and zooplankton) that had non-zero  $L1$  (suggesting sensitivity) were retained for identifiability analysis.

## 2.3 Identifiability and selecting parameter subsets

Identifiability of parameter subsets was estimated from the minimum eigenvector of the cross-product of a selected sensitivity matrix (Brun et al. 2001, Omlin et al. 2001a):

$$\gamma = \frac{1}{\sqrt{\min(\text{EV}[\hat{S}^\top \hat{S}])}}$$

where  $\gamma$  ranges from one to infinity for perfectly identifiable (orthogonal) or unidentifiable (perfectly collinear) results for parameters in a sensitivity matrix  $S$ . The sensitivity functions were supplied as a matrix  $\hat{S}$  with rows  $i$  and columns  $j$  (eq. (1)) that described deviations of predicted  $\text{O}_2$  from the default parameter values. The matrix  $\hat{S}$  was first normalized by dividing by the square root of the summed residuals (Omlin et al. 2001a, Soetaert and Petzoldt 2010).

The collinearity index  $\gamma$  provides a measure of the linear dependence between sensitivity functions described above for subsets of parameters. Estimates of  $\gamma$  greater than 10-15 suggest parameter sets are poorly identifiable (Brun et al. 2001, Omlin et al. 2001a), meaning parameter values that maximize precision on a calibration dataset are inestimable by conventional optimization algorithms given similar effects of the selected parameters on  $\text{O}_2$ . Greater sensitivity of a state variable to a subset of parameters does not always imply better identifiability if the individual effects are similar. An intuitive interpretation of  $\gamma$  is provided by Brun et al. (2001) such that a change in a state variable caused by a change in one parameter can be offset by the fraction  $1 - 1/\gamma$  by the remaining parameters. That is,  $\gamma = 10$  suggests the relative change in  $\text{O}_2$  for an arbitrary parameter in the selected set can be compensated for by 90% with changes in the other parameters.

Initial analyses suggested that considerably limited subsets of parameters were identifiable of the 51 evaluated for the FishTank model. Given this limitation, parameter selection must consider the competing objectives of increased precision with parameter inclusion and reduced identifiability as it relates to optimization. An additional challenge is the excessively high number of combinations of parameter sets, which complicates selection given sensitivity differences and desired ecological categories of each parameter (e.g., practitioners may only be interested in optics parameters). For example, Fig. 1 provides a simple graphic of the unique number of combinations that are possible for different subsets of ‘complete’ parameter sets of different sizes (i.e., based on  $n$  choose  $k$  combinations equal to  $n! / (k! (n - k)!)$ ). The number of unique combinations increases with the total parameters in the set and is also maximized for moderate selections (e.g., selecting half the total). For example, over  $10^{14}$  combinations are possible by

selecting 25 parameters from a set of 50. Accordingly, parameter selection is complicated by differing sensitivity, identifiability limits for parameter subsets, and the difficulty of choosing from many combinations.

A set of heuristics was developed that address the tradeoff in model complexity and identifiability given the challenges described above (see also Wagener et al. 2001a). These rulesets were developed with the assumption that parameters will be selected with preference for those with high sensitivity and identifiability based on  $\gamma < 15$  as an acceptable threshold for subsets (e.g., 93% accountability). Selection heuristics also recognized that parameter categories (i.e., optics, organic matter, phytoplankton, temperature, zooplankton) may have unequal preferences by model users given questions of interest. In all selection scenarios, parameters were selected by decreasing sensitivity starting with the most sensitive until identifiability did not exceed  $\gamma = 15$  where selections were 1) blocked within parameter category, 2) independent of parameter category, 3) or considering all categories equally. The selection rules produced seven subsets of parameters that could further be used to optimize model calibration.

## 2.4 Observational and structural uncertainty

In addition to parameter uncertainty, the effects of observational and structural uncertainty on the sensitivity analyses were evaluated by changing the initial conditions and structural components, respectively, from the default model setup. First, observational uncertainty (i.e., effects of observed data on model output) was evaluated by varying the initial conditions that were based on observational data from research cruises in the northern GOM (Murrell et al. 2014). Uncertainty in these data translates directly to uncertainty that can influence results of the sensitivity analysis. For example, the sensitivity of  $O_2$  to variation in the half-saturation constants for phytoplankton (the concentration supporting half the maximum uptake rate of nutrients) will vary given the initial nutrient concentrations (Eppley et al. 1969). Further, changes in the ratio between nitrogen and phosphorus could affect sensitivity depending on the limiting nutrient. Parameter sensitivity was re-evaluated by varying all initial conditions that were non-zero by different seasonal means based on averages of water quality data across stations and years. April and September seasonal averages of the observed data were used to evaluate the effects of conditions that were typical of spring and late summer on the LCS (Table 1).

The effects of model structure on parameter sensitivity (i.e., structural uncertainty) were

evaluated by changing specific components of the model. The FishTank model includes several ecosystem processes or characteristics that can be included based on expected conditions, available data, or desired complexity. These ‘switches’ are conceptually different from model parameters as they allow the inclusion or exclusion of explicit equations or processes. Switches in FishTank include different structural equations for the vertical attenuation of light through the water column (inherent or apparent optical properties, [Penta et al. 2009](#), [Eldridge and Roelke 2010](#)) and chlorophyll to carbon ratio models (fixed or dynamic given light and nutrients, [Cloern et al. 1995](#)). Several switches also affect phytoplankton growth including different models for specific growth and effects of temperature, light dependence, nutrient uptake, and internal cell quotas ([Lehrter et al. in review](#), references therein).

Parameter sensitivity was evaluated by comparing the results from the default model setup to a more complex setup with alternative switches (Table 2). The scenarios used switches for different equations to represent structural relationships of phytoplankton growth patterns with temperature, nutrient uptake, cell quotas, <sup>acro:chl-a</sup>chlorophyll *a* (chl-*a*) to carbon ratios, photosynthesis dynamics, and specific growth limits. The default scenario modelled phytoplankton growth with temperature as a sigmoidal function ([Eldridge and Roelke 2010](#)), nutrient uptake as Michaelis-Menten kinetics ([Dugdale and Goering 1967](#)), internal cell quotas following [Droop \(1973\)](#), chl-*a* to carbon ratios as a simple regression ([Murrell et al. 2014](#)), light-dependence of photosynthesis with photoinhibition ([Platt et al. 1980](#)), and a specific growth rate following Leibig’s law of the minimum. Conversely, the complex scenario used switches that modelled relationships between phytoplankton growth with temperature using the Arrhenius model ([Geider et al. 1997](#)), nutrient uptake as proposed by [Lehman et al. \(1975\)](#) and modified in [Geider et al. \(1998\)](#), internal cell quotas following [Flynn \(2003\)](#), chl-*a* to carbon ratios following [Cloern et al. \(1995\)](#), light-dependence of photosynthesis that is nutrient dependent ([Flynn 2003](#)), and a specific growth rate that is nutrient dependent. Complete details are provided as supplementary material to [Lehrter et al. in review](#).

## 2.5 Extension to other state variables

The above analyses were repeated for additional state variables estimated by FishTank to provide further descriptions of ecological dynamics that are relevant for hypoxia. In addition to O<sub>2</sub>, other state variables that were evaluated were ammonium, chl-*a*, irradiance, nitrate, <sup>acro:pom</sup>

particulate organic matter (POM), <sup>acro:dom</sup>dissolved organic matter (DOM), and phosphorus. Particulate and dissolved organic matter were estimated as the summation of the respective outputs for organic matter from phytoplankton (*OM1\_A*, *OM2\_A*) and fecal pellets from zooplankton (*OM1\_Z*, *OM2\_Z*, see [Lehrter et al. in review](#)).

### 3 Results

#### 3.1 Local sensitivity analysis

Local sensitivity analyses showed that  $O_2$  was sensitive to perturbations in 38 of the 51 (75% of total) evaluated parameters in FishTank (default panel Fig. 2, Table 3). Within each parameter category,  $O_2$  was sensitive to three parameters for optics (75% of all optic parameters), eight for organic matter (67%), 16 for phytoplankton (73%), one for temperature (50%), and 10 for zooplankton (91%). Although  $O_2$  had the greatest sensitivity to parameters in the zooplankton category (as percentage of total), the relative effects varied. Among all parameters, sensitivity values ranged from  $L1 = 8.34 \times 10^{-8}$  for *QminP* (phytoplankton) to 0.05 for *umax* (phytoplankton), whereas average sensitivity among all parameters was  $L1 = 0.01$ . Within categories (excluding temperature), sensitivity ranged from  $4.39 \times 10^{-5}$  (*astarOMA*) to  $7.51 \times 10^{-4}$  (*astar490*) for optics,  $4.17 \times 10^{-4}$  (*KNH4*) to 0.01 (*KGI*) for organic matter,  $8.34 \times 10^{-8}$  (*QminP*) to 0.05 (*umax*) for phytoplankton, and  $3.69 \times 10^{-5}$  (*ZQp*) to 0.05 (*ZKa*) for zooplankton (Table 3). Average sensitivity values in each category were  $L1 = 2.81 \times 10^{-4}$  for optics, 0 for organic matter, 0.02 for temperature, 0.01 for phytoplankton, and 0.01 for zooplankton.

Local sensitivity analyses for the additional state variables (ammonium, chl-*a*, irradiance, nitrate, POM, DOM, and phosphorus) had similar results as  $O_2$  with some exceptions (Fig. 2 and Tables S1 to S7). All additional variables were sensitive to the same parameters (38 of 51 evaluated), although average sensitivity differed between variables. Average  $L1$  ranged from 0.02 for irradiance (Table S3) to 0.71 for DOM (Table S6). All average sensitivity values for the state variables were higher than the average for  $O_2$  ( $L1 = 0.01$ ). For each variable,  $L1$  ranged from  $2.24 \times 10^{-6}$  (*QminP*) to 8.49 (*mA*) for ammonium (Table S1),  $1.38 \times 10^{-6}$  (*QminP*) to 13.94 (*mA*) for chl-*a* (Table S2),  $1.92 \times 10^{-7}$  (*QminP*) to 0.13 (*ZKa*) for irradiance (Table S3),  $6.67 \times 10^{-7}$  (*QminP*) to 8.49 (*umax*) for nitrate (Table S4),  $6.41 \times 10^{-5}$  (*KNH4*) to 7.22 (*mA*) for

POM (Table S5),  $7.41 \times 10^{-5}$  (*KNH4*) to 14.25 (*mA*) for DOM (Table S6), and  $8.21 \times 10^{-7}$  (*QminP*) to 1.47 (*ZKa*) for phosphate (Table S7). For the parameter categories, ammonium was most sensitive to phytoplankton parameters (average  $L1 = 0.8$  across all parameters in the category), chl-*a* to phytoplankton ( $L1 = 1.14$ ), irradiance to zooplankton ( $L1 = 0.03$ ), nitrate to zooplankton ( $L1 = 1.06$ ), POM to temperature ( $L1 = 0.86$ ), DOM to temperature ( $L1 = 1.48$ ), and phosphate to zooplankton ( $L1 = 0.31$ ). Finally, average sensitivity between parameter categories independent of the state variables ranged from 0.01 for optics (average  $L1$  across all variables) to 0.62 for phytoplankton.

### 3.2 Subset identifiability

The identifiability analyses suggested that many parameter subsets exceeded the thresholds of  $\gamma = 10, 15$ , providing further justification for using selection heuristics for parameter optimization. Results for  $O_2$  are provided first to demonstrate general concepts for the identifiability analyses, followed by an extension to the remaining state variables. Parameter identifiability (as  $\gamma$ ) for  $O_2$  increased at different rates with increasing size of parameter subsets depending on the parameter category or the number of top parameters that were selected (Fig. 3). By category, identifiability was lowest for all combinations of parameter subsets (from two to many parameters) in the phytoplankton (60% less than  $\gamma = 15$ , 43% less than  $\gamma = 10$ ) and zooplankton categories (53.1% less than  $\gamma = 15$ , 40% less than  $\gamma = 10$ ), whereas all combinations were identifiable for optics (100% less than  $\gamma = 15$ , 100% less than  $\gamma = 10$ ) and a majority identifiable for organic matter (91.9% less than  $\gamma = 15$ , 76.5% less than  $\gamma = 10$ ) combinations were identifiable. Identifiability for parameters in the temperature category was not evaluated because  $O_2$  was sensitive to only one parameter (i.e.,  $\gamma = 1$ ). Parameter combinations for choosing from the top, top two, top three, and top four parameters in each category together had decreasing identifiability with the increasing size of the selection pool (e.g., top one versus top four parameters, Fig. 3). The percentage of parameter subsets that were below the acceptable thresholds for identifiability was 100% less than  $\gamma = 15$  and 100% less than  $\gamma = 10$  for the top parameters in each category, 90.6% and 80.7% for the top two, 80.7% and 70.9% for the top three, and 55.8% and 45.7% for the top four. Results for the remaining state variables had similar patterns in identifiability with increasing size of parameter subsets and selection categories, although differences in identifiability between state variables was observed (Fig. 4). Most

notably, nitrate was consistently the least identifiable variable for all selection heuristics (highest  $\gamma$ ), whereas O<sub>2</sub> was most identifiable.

An alternative view of the results in Fig. 3 can be used to demonstrate the effects of parameter selection criteria and number of parameters in the selection pool on identifiability. Fig. 5 shows the percentage of identifiable parameter sets for O<sub>2</sub> using the same selection criteria in Fig. 3, i.e., selection of parameters only within parameter categories and selection of the top sensitive parameters regardless of category. Fig. 5 is conceptually similar to Fig. 3, with the added effect of a chosen  $\gamma$  threshold on identifiability. Previous studies have provided general rules for  $\gamma$  thresholds (Brun et al. 2001, Omlin et al. 2001a), such that exact values beyond which model calibration fails could vary for the given model and optimization method. The selected  $\gamma$  thresholds are somewhat arbitrary, although the results show differences that have implications for parameter selection for model calibration. In general, identifiability decreases with the addition of parameters, although the rate of decrease depends on the selected threshold for  $\gamma$ . More conservative values for  $\gamma$  (e.g.,  $\gamma = 5$ ) were more sensitive to the number of parameters in a subset. Notable differences in identifiability were also observed by selection criteria (within categories or top parameters only), which further supports results in Figs. 3 and 4.

An evaluation of the effects of individual parameters on  $\gamma$  further suggested that some parameters have disproportionate effects on identifiability. Based on  $\gamma = 15$ , Fig. 3 suggests that most parameter sets for organic matter were identifiable, regardless of how many parameters were selected (i.e., two through eight). Because identifiability of the organic matter parameters was generally acceptable, identification of one or more redundant parameters that are inflating  $\gamma$  values could provide useful information. Fig. 6 shows an alternative view of identifiability of O<sub>2</sub> with exclusion and inclusion of individual parameters in different sets for the organic matter category. Collinearity increases with more parameters included in a subset, although the increase varies depending on which parameter was included or excluded from the set. For example, inclusion of *KNO3* in a parameter set almost always inflated  $\gamma$ . All parameter subsets that did not include *KNO3* were well below  $\gamma = 15$ , suggesting that removal of this parameter improves identifiability. Interestingly, the inclusion of some parameters caused a reduction in  $\gamma$ , which contradicts the general rule that more parameters caused reduced identifiability. For example, parameter sets that included *KGcdom* generally had lower  $\gamma$  values relative to those that excluded

the parameter.

### 3.3 Parameter selection

The above results demonstrated that each state variables differed in the magnitudes of sensitivity for each parameter and the number of identifiable subsets, where the latter varied by identifiability thresholds and parameter selection criteria. These results further underscore the need for explicit selection heuristics for parameters to calibrate for improving model performance. Results for each of the three selection heuristics (blocked by parameter category, independent of category, all categories equally) applied to each state variable differed in the number of selected parameters and distribution of parameters within each category (Tables 4 to 6). In general, a correspondence was observed between the number of parameters that were selected given the threshold of  $\gamma = 15$  and relative identifiability between the state variables. As noted above, nitrate was the least identifiable variable (Fig. 4), whereas other variables (e.g.,  $O_2$ , irradiance) were more identifiable. The constraints on relative identifiability between variables were demonstrated with the selection heuristics. For example, heuristics for nitrate typically selected only one or two parameters that met the criteria as compared to more identifiable variables that included several parameters that were identifiable. Overall, the first selection heuristic demonstrated that the number of parameters chosen by parameter category differed independently of the state variables (Table 4). The number of selected parameters averaged across state variable in decreasing order was 4.25 parameters (phytoplankton), 3.5 (organic matter), 2.75 (optics), and 2.38 (zooplankton). These rankings were independent of parameter sensitivity and identifiability in each category. The second and third selection heuristics (Tables 5 and 6) were similar, although more parameters were generally selected for the third heuristic.

Fig. 7 demonstrates parameter selection for all state variables following the second heuristic where parameters were chosen by decreasing sensitivity independent of parameter categories (exact values are shown in Table 5). The y-axis on the plot shows the relative identifiability values with the addition of parameters from one to many on the x-axis (from left to right). The second to last parameter for each variable is the last parameter selected within the potential threshold of  $\gamma = 15$ . Interestingly, the last parameter shown for most of the state variables caused a relatively large increase in  $\gamma$  that was disproportionate to the combined identifiability of the preceding parameter set. For most variables, the phytoplankton edibility

vector for zooplankton, *ediblevector*(Z1), caused a dramatic increase in  $\gamma$  with inclusion in the parameter set. In addition to demonstrating the approach for selection with the second heuristic, Fig. 7 provides an alternative approach to identifying parameters that are disproportionately redundant within a given parameter set. This information is useful if additional parameter selection rules are developed independently of those proposed herein.

### 3.4 Observational and structural uncertainty

Both the relative  $L1$  estimates and number of parameters that affected state variables were sensitive to variation in the initial conditions (observation effects) and structural changes in the model. Visual comparison of sensitivity values ( $L1$ ) for the default model setup showed that all state variables were sensitive to  $vmaxSi$  after changing the initial conditions to April or September conditions (Fig. 2). State variables were also sensitive to  $Ksi$  for only the September conditions. Changing the model structure from the default (simple) to the complex setup showed state variables were also sensitive to  $KQn$  and  $Tref(nospA+nospZ)_{z1}$ . Changes in the sensitivity of individual parameters were also observed, most notably as a disproportionate increase in  $L1$  for ammonium, chl-*a*, POM, and DOM to  $mA$  and  $Tref(nospA+nospZ)_{p1}$  using the complex model setup. Summaries by parameter categories of the effects of initial conditions and structural changes are shown in Table 7 and Fig. 8. Changes in average sensitivity using April and September initial conditions showed most variables were less sensitive to parameters in the optics, temperature, and zooplankton categories, whereas increased sensitivity was generally observed for parameters in the organic matter and phytoplankton categories. Some exceptions were observed, such as a decrease in nitrogen sensitivity to phytoplankton parameters. Effects of structural complexity were most apparent as an increase in sensitivity of state variables to phytoplankton and temperature parameters, as noted for the individual variables in Fig. 2.

Table 1: Initial conditions that were varied to evaluate effects of observational uncertainty on parameter sensitivity. April and September values are based on seasonal averages from water quality samples of the LCS. All units are  $\mu\text{mol L}^{-1}$ .  
tab:inits

Variables	Default	April	September
Dissolved Inorganic Carbon	2134	2096.5	2133.37
Ammonium	1.09	1.79	0.35
Nitrate	71.4	3.75	2.04
Dissolved Oxygen	172	194.47	152.57
Phosphate	1.81	0.23	0.42
Silica	71.4	5.84	9.77

Table 2: Model switches that were used to evaluate effects of structural uncertainty on parameter sensitivity. Complete details and equations are provided as supplementary material to [Lehrter et al. in review](#).  
tab:strcs

Switch type	Default	Complex
Temperature	sigmoidal (Eldridge and Roelke 2010)	Arrhenius (Geider et al. 1997)
Uptake	Michaelis-Menten (Dugdale and Goering 1967)	Geider (Lehman et al. 1975, Geider et al. 1998)
Quota	Droop (Droop 1973)	Flynn (Flynn 2003)
Chla:C	regression (Murrell et al. 2014)	Cloern (Cloern et al. 1995)
Photosynthesis	photoinhibition (Platt et al. 1980)	nutrient dependent
Specific growth rate	Leibig's minimum	nutrient dependent

Table 3: Sensitivity of O<sub>2</sub> to perturbations of individual parameters. Sensitivities are based on a 50% increase from the initial parameter value, where *L1* summarizes differences in model output from the default (see eq. (2)). Parameters that did not affect O<sub>2</sub> are not shown. Parameters are grouped by categories as optics, temperature, phytoplankton, zooplankton, and organic matter. <sup>tab: dosens</sup>

Description	Parameter	L1
<b>Optics</b>		
Chla specific absorption at 490 nm	<i>astar490</i>	$7.51 \times 10^{-4}$
OMZ specific absorption at 490 nm	<i>astarOMZ</i>	$4.92 \times 10^{-5}$
OMA specific absorption at 490 nm	<i>astarOMA</i>	$4.39 \times 10^{-5}$
<b>Temperature</b>		
Optimum temperature for growth(C)	<i>Tref(nospA+nospZ)<sub>p1</sub></i>	0.02
<b>Phytoplankton</b>		
maximum growth rate	<i>umax</i>	0.05
mortality coefficient	<i>mA</i>	0.02
initial slope of the photosynthesis-irradiance relationship	<i>alpha</i>	0.02
edibility vector for Z1	<i>ediblevector(Z1)</i>	0.02
phytoplankton carbon/cell	<i>Qc</i>	0.01
phytoplankton growth respiration coefficient	<i>respg</i>	$8.36 \times 10^{-3}$
N-uptake rate measured at umax	<i>vmaxN</i>	$8.12 \times 10^{-3}$
phytoplankton basal respiration coefficient	<i>respb</i>	$6.94 \times 10^{-3}$
Phytoplankton threshold for grazing, is multiplied by VOLcell	<i>Athresh</i>	$4.57 \times 10^{-3}$
minimum N cell-quota	<i>QminN</i>	$4.32 \times 10^{-3}$
P-uptake rate measured at umax	<i>vmaxP</i>	$4.27 \times 10^{-3}$
coefficient for non-limiting nutrient	<i>aN</i>	$4.23 \times 10^{-3}$
phytoplankton volume/cell	<i>volcell</i>	$4.13 \times 10^{-3}$
half-saturation constant for P	<i>Kp</i>	$2.9 \times 10^{-3}$
half-saturation constant for N	<i>Kn</i>	$2.77 \times 10^{-4}$
minimum P cell-quota	<i>QminP</i>	$8.34 \times 10^{-8}$
<b>Zooplankton</b>		
half saturation coefficient for grazing	<i>ZKa</i>	0.05
zooplankton nitrogen/individual	<i>ZQn</i>	0.02
Zooplankton mortality constant for quadratic mortality	<i>Zm</i>	0.02
maximum growth rate of zooplankton	<i>Zumax</i>	0.02
assimilation efficiency as a fraction of ingestion	<i>Zeffic</i>	0.01
proportion of grazed phytoplankton lost to sloppy feeding	<i>Zslop</i>	$7.78 \times 10^{-3}$
Zooplankton growth-dependent respiration factor	<i>Zrespg</i>	$5.32 \times 10^{-3}$
Zooplankton biomass-dependent respiration factor	<i>Zrespb</i>	$2.96 \times 10^{-3}$
zooplankton carbon/individual	<i>ZQc</i>	$9.38 \times 10^{-5}$
zooplankton phosphorus/individual	<i>ZQp</i>	$3.69 \times 10^{-5}$
<b>Organic Matter</b>		
turnover rate for OM1A and OM1Z	<i>KG1</i>	$6.15 \times 10^{-3}$
turnover rate for OM2A and OM2Z	<i>KG2</i>	$3.14 \times 10^{-3}$
O2 concentration that inhibits denitrification	<i>KstarO2</i>	$3.04 \times 10^{-3}$
decay rate of CDOM, 1/day	<i>KGcdom</i>	$2.98 \times 10^{-3}$
half-saturation concentration for O2 utilization	<i>KO2</i>	$5.85 \times 10^{-4}$
half-saturation concentration for NO3 used in denitrification	<i>KNO3</i>	$5.8 \times 10^{-4}$
maximum rate of nitrification per day	<i>nitmax</i>	$4.99 \times 10^{-4}$
NH4 rate constant for nitrification	<i>KNH4</i>	$4.17 \times 10^{-4}$

\*Temperature parameters apply separately to phytoplankton (*p1*, one group) or zooplankton (*z1*, one group), denoted by subscripts

Table 4: Parameter identifiability (as  $\gamma$ , eq. (3)) by category for relevant state variables. Selections followed the first heuristic where parameters were selected within categories from most to least sensitive until  $\gamma > 15$ . Rank describes the relative parameter sensitivity in each category for each state variable. Duplicate parameters and ranks in the first two columns apply only to  $\gamma$  values in the same row (i.e., the top-ranked parameter could vary for each variable).

Table 7: Changes in mean sensitivity of state variables by parameter categories to different initial conditions and structural components of the model. Changes show the difference in average sensitivity from results using the default model setup. Sensitivities are based on average  $L1$  (see eq. (2)) values of the state variables to changes in parameters in each parameter category. Increases in average sensitivity are in bold. Medians and ranges of sensitivity values for the different conditions are shown in Fig. 8. <sup>tab:inistrchg</sup>

State variables by parameter category	Default sensitivity	Change		
		Initial: April	Initial: September	Structure: complex

Fig. 1: Examples of unique parameter combinations from different parameter sets and number of selected parameters. The number of combinations are shown for increasing numbers of selected parameters from the total in the set, where 50 parameter sets are shown each with one through 50 total parameters. Note that the number of unique combinations is shown as the natural-log.

Fig. 1: combnex

Fig. 2: Sensitivity values (L1, eq. (2)) of all state variables to changes in parameter values using default conditions, changes in initial conditions (April, September seasonal means, Table 1), and changes in structural complexity (Table 2). Parameters are grouped by category: optics, organic matter, phytoplankton, zooplankton, temperature, and zoplankton. See Table 3 for L1 values for  $O_2$  and Tables S1 to S7 for the other state variables.

fig:sensalltile

Fig. 3: Identifiability (as  $\gamma$ , eq. (3)) of parameter subsets for  $O_2$ . Plots in (a) show identifiability by parameter categories and (b) shows identifiability by selecting the top 1 through 4 parameters in all categories. Lines represent identifiability ranges for the possible combinations given the number of parameters in the set. The temperature category is not shown because  $O_2$  was sensitive to only one parameter (i.e.,  $\gamma = 1$ ).

fig:identplo

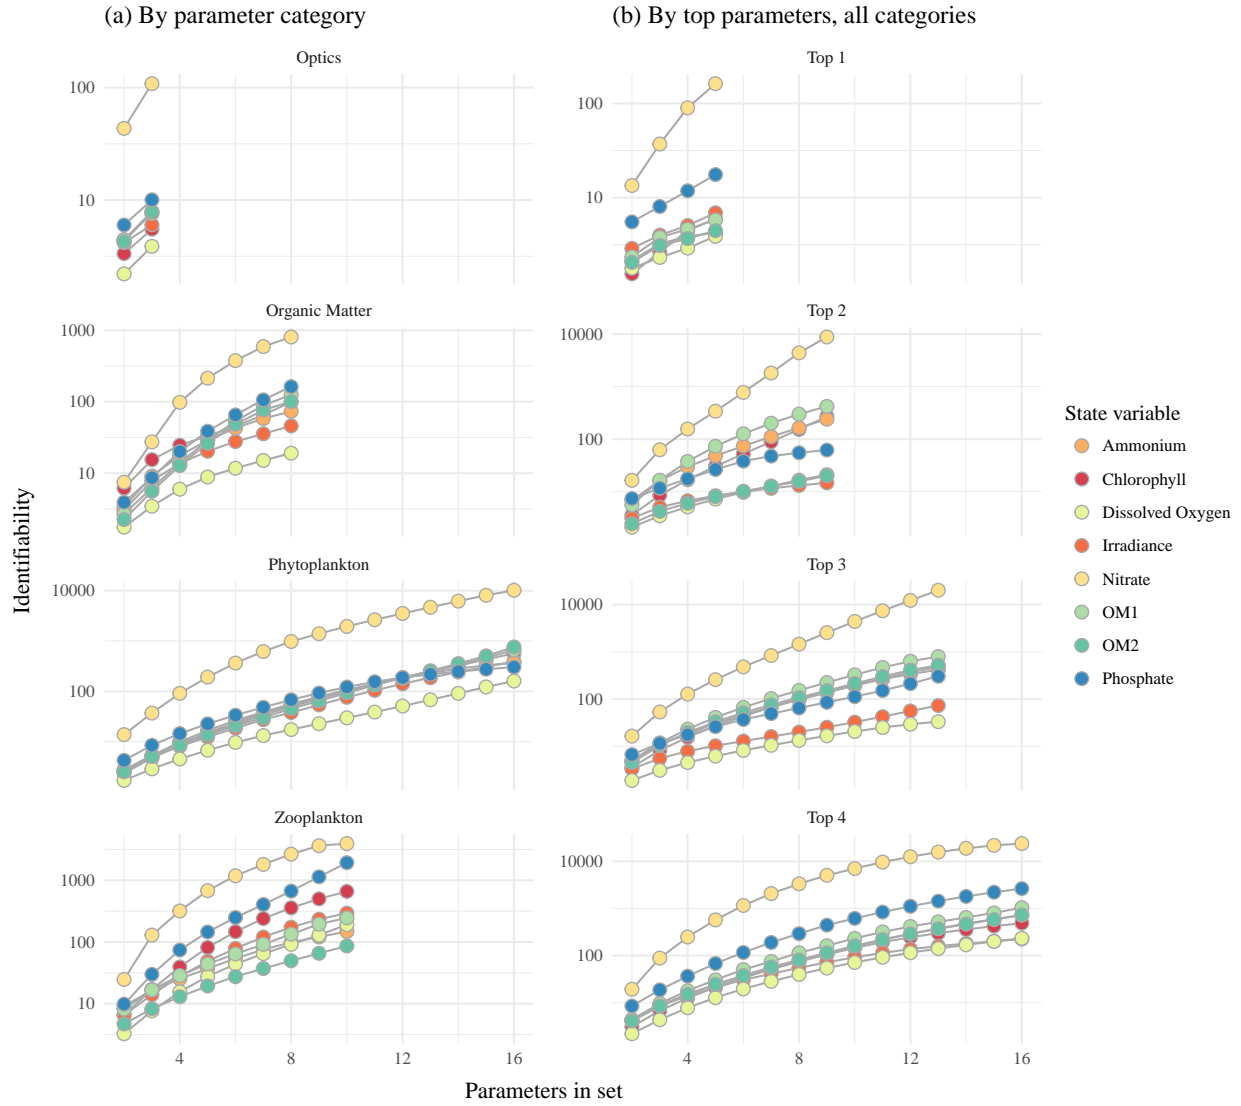

Fig. 4: Average identifiability (as  $\gamma$ , eq. (3)) of parameter subsets for all state variables. Plots in (a) show identifiability by parameter categories and (b) shows identifiability by selecting the top 1 through 4 parameters in all categories. Identifiability was averaged for all combinations in a parameter set to evaluate relative differences between state variables. The temperature category is not shown because all state variables were sensitive to only one parameter (i.e.  $\gamma = 1$ ).

Fig. 5: Percent of identifiable parameter sets for  $O_2$  at different  $\gamma$  thresholds, selection criteria, and total number of parameters in the set. Thresholds varied from  $\gamma = 2$  to 20 such that sets with  $\gamma$  below a threshold were considered identifiable relative to the value. Plots in (a) show percent of identifiable sets by selecting parameters within categories and (b) shows percent identifiable by selecting from the top 1 through 4 parameters in all categories. Percent identifiable was based on all sets in Fig. 3.

fig:percthresh

Fig. 6: Identifiability (as  $\gamma$ , eq. (3)) for  $O_2$  of organic matter parameters for subset combinations in Fig. 3. Identifiability is evaluated for subsets that excluded and included the parameters at the top of each plot. Identifiability of including all eight parameters is in Fig. 3. Grey lines indicate potential thresholds at  $\gamma = 10, 15$  for maximum acceptable identifiability.

fig:excl

Fig. 7: Identifiability (as  $\gamma$ , eq. (3)) of selecting parameters for all state variables. Parameters are selected by decreasing sensitivity independent of parameter categories. Grey lines indicate potential thresholds at  $\gamma = 10, 15$  for maximum acceptable identifiability. Selection stops after  $\gamma > 15$ .

fig:heurist\_stts

Fig. 8: Summaries of changes in parameter sensitivity values (L1, eq. (2)) from the default model conditions. Sensitivity was re-evaluated using initial conditions as seasonal means for April and September, and added structural complexity. Sensitivity is summarized as the minimum, median, and maximum for each state variable separated by parameter categories. Changes in average sensitivity from the default model conditions are in Table 7.

fig:inistrsumm

Table S1: Sensitivity of ammonium to perturbations of individual parameters. Sensitivities are based on a 50% increase from the initial parameter value, where  $L1$  summarizes differences in model output from the default (see eq. (2)). Parameters that did not affect ammonium are not shown. Parameters are grouped by categories as optics, temperature, phytoplankton, zooplankton, and organic matter. <sup>tab:nh4sens</sup>

Table S4: Sensitivity of nitrate to perturbations of individual parameters. Sensitivities are based on a 50% increase from the initial parameter value, where *L1* summarizes differences in model output from the default (see eq. (2)). Parameters that did not affect nitrate are not shown. Parameters are grouped by categories as optics, temperature, phytoplankton, zooplankton, and organic matter. tab: no3sens

Description	Parameter	L1
<b>Optics</b>		
Chla specific absorption at 490 nm	<i>astar490</i>	0.02
OMZ specific absorption at 490 nm	<i>astarOMZ</i>	$1.27 \times 10^{-3}$
OMA specific absorption at 490 nm	<i>astarOMA</i>	$1.19 \times 10^{-3}$
<b>Temperature</b>		
Optimum temperature for growth(C)	<i>Tref(nospA+nospZ)<sub>p1</sub></i>	0.3
<b>Phytoplankton</b>		
maximum growth rate	<i>umax</i>	8.49
phytoplankton carbon/cell	<i>Qc</i>	0.89
initial slope of the photosynthesis-irradiance relationship	<i>alpha</i>	0.7
edibility vector for Z1	<i>ediblevector(Z1)</i>	0.33
mortality coefficient	<i>mA</i>	0.27
Phytoplankton threshold for grazing, is multiplied by VOLcell	<i>Athresh</i>	0.2
N-uptake rate measured at umax	<i>vmaxN</i>	0.19
coefficient for non-limiting nutrient	<i>aN</i>	0.13
phytoplankton growth respiration coefficient	<i>respg</i>	0.11
phytoplankton volume/cell	<i>volcell</i>	0.1
P-uptake rate measured at umax	<i>vmaxP</i>	0.1
half-saturation constant for P	<i>Kp</i>	0.09
minimum N cell-quota	<i>QminN</i>	0.09
phytoplankton basal respiration coefficient	<i>respb</i>	0.07
half-saturation constant for N	<i>Kn</i>	$7.06 \times 10^{-3}$
minimum P cell-quota	<i>QminP</i>	$6.67 \times 10^{-7}$
<b>Zooplankton</b>		
half saturation coefficient for grazing	<i>ZKa</i>	7.59
zooplankton nitrogen/individual	<i>ZQn</i>	1.17
Zooplankton mortality constant for quadratic mortality	<i>Zm</i>	0.7
maximum growth rate of zooplankton	<i>Zumax</i>	0.34
proportion of grazed phytoplankton lost to sloppy feeding	<i>Zslop</i>	0.26
assimilation efficiency as a fraction of ingestion	<i>Zeffic</i>	0.25
Zooplankton growth-dependent respiration factor	<i>Zrespg</i>	0.17
Zooplankton biomass-dependent respiration factor	<i>Zrespb</i>	0.1
zooplankton carbon/individual	<i>ZQc</i>	$3.8 \times 10^{-3}$
zooplankton phosphorus/individual	<i>ZQp</i>	$8.59 \times 10^{-4}$
<b>Organic Matter</b>		
O2 concentration that inhibits denitrification	<i>KstarO2</i>	0.78
half-saturation concentration for NO3 used in denitrification	<i>KNO3</i>	0.07
decay rate of CDOM, 1/day	<i>KGcdom</i>	0.04
half-saturation concentration for O2 utilization	<i>KO2</i>	0.03
turnover rate for OM1A and OM1Z	<i>KG1</i>	0.02
turnover rate for OM2A and OM2Z	<i>KG2</i>	0.01
maximum rate of nitrification per day	<i>nitmax</i>	$9.96 \times 10^{-3}$
NH4 rate constant for nitrification	<i>KNH4</i>	$9.87 \times 10^{-3}$

Table S5: Sensitivity of POM to perturbations of individual parameters. Sensitivities are based on a 50% increase from the initial parameter value, where *L1* summarizes differences in model output from the default (see eq. (2)). Parameters that did not affect POM are not shown. Parameters are grouped by categories as optics, temperature, phytoplankton, zooplankton, and organic matter. <sup>tab:om1sens</sup>

Description	Parameter	L1
<b>Optics</b>		
Chla specific absorption at 490 nm	<i>astar490</i>	0.03
OMA specific absorption at 490 nm	<i>astarOMA</i>	$1.73 \times 10^{-3}$
OMZ specific absorption at 490 nm	<i>astarOMZ</i>	$1.49 \times 10^{-3}$
<b>Temperature</b>		
Optimum temperature for growth(C)	<i>Tref(nospA+nospZ)<sub>p1</sub></i>	0.86
<b>Phytoplankton</b>		
mortality coefficient	<i>mA</i>	7.22
edibility vector for Z1	<i>ediblevector(Z1)</i>	0.9
maximum growth rate	<i>umax</i>	0.89
phytoplankton carbon/cell	<i>Qc</i>	0.67
initial slope of the photosynthesis-irradiance relationship	<i>alpha</i>	0.67
N-uptake rate measured at umax	<i>vmaxN</i>	0.45
phytoplankton growth respiration coefficient	<i>respg</i>	0.29
phytoplankton basal respiration coefficient	<i>respb</i>	0.24
Phytoplankton threshold for grazing, is multiplied by VOLcell	<i>Athresh</i>	0.22
minimum N cell-quota	<i>QminN</i>	0.21
coefficient for non-limiting nutrient	<i>aN</i>	0.14
half-saturation constant for P	<i>Kp</i>	0.11
phytoplankton volume/cell	<i>volcell</i>	0.1
P-uptake rate measured at umax	<i>vmaxP</i>	0.09
half-saturation constant for N	<i>Kn</i>	0.01
minimum P cell-quota	<i>QminP</i>	$7.35 \times 10^{-4}$
<b>Zooplankton</b>		
maximum growth rate of zooplankton	<i>Zumax</i>	0.96
half saturation coefficient for grazing	<i>ZKa</i>	0.79
assimilation efficiency as a fraction of ingestion	<i>Zeffic</i>	0.54
zooplankton nitrogen/individual	<i>ZQn</i>	0.49
Zooplankton mortality constant for quadratic mortality	<i>Zm</i>	0.39
proportion of grazed phytoplankton lost to sloppy feeding	<i>Zslop</i>	0.27
Zooplankton growth-dependent respiration factor	<i>Zrespg</i>	0.16
Zooplankton biomass-dependent respiration factor	<i>Zrespb</i>	0.12
zooplankton carbon/individual	<i>ZQc</i>	$9.64 \times 10^{-3}$
zooplankton phosphorus/individual	<i>ZQp</i>	$1.06 \times 10^{-3}$
<b>Organic Matter</b>		
turnover rate for OM1A and OM1Z	<i>KG1</i>	0.92
decay rate of CDOM, 1/day	<i>KGcdom</i>	0.07
half-saturation concentration for O2 utilization	<i>KO2</i>	0.04
O2 concentration that inhibits denitrification	<i>KstarO2</i>	0.02
turnover rate for OM2A and OM2Z	<i>KG2</i>	0.01
half-saturation concentration for NO3 used in denitrification	<i>KNO3</i>	$3.72 \times 10^{-3}$
maximum rate of nitrification per day	<i>nitmax</i>	$6.98 \times 10^{-5}$
NH4 rate constant for nitrification	<i>KNH4</i>	$6.41 \times 10^{-5}$

Table S6: Sensitivity of dissolved organic matter to perturbations of individual parameters. Sensitivities are based on a 50% increase from the initial parameter value, where  $L1$  summarizes differences in model output from the default (see eq. (2)). Parameters that did not affect dissolved organic matter are not shown. Parameters are grouped by categories as optics, temperature, phytoplankton, zooplankton, and organic matter. <sup>tab:om2sens</sup>

Description	Parameter	L1
<b>Optics</b>		
Chla specific absorption at 490 nm	<i>astar490</i>	0.04
OMA specific absorption at 490 nm	<i>astarOMA</i>	$2.48 \times 10^{-3}$
OMZ specific absorption at 490 nm	<i>astarOMZ</i>	$2.04 \times 10^{-3}$
<b>Temperature</b>		
Optimum temperature for growth(C)	<i>Tref(nospA+nospZ)<sub>p1</sub></i>	1.48
<b>Phytoplankton</b>		
mortality coefficient	<i>mA</i>	14.25
maximum growth rate	<i>umax</i>	1.11
edibility vector for Z1	<i>ediblevector(Z1)</i>	0.94
N-uptake rate measured at umax	<i>vmaxN</i>	0.86
initial slope of the photosynthesis-irradiance relationship	<i>alpha</i>	0.85
phytoplankton carbon/cell	<i>Qc</i>	0.67
phytoplankton growth respiration coefficient	<i>respg</i>	0.36
phytoplankton basal respiration coefficient	<i>respb</i>	0.29
coefficient for non-limiting nutrient	<i>aN</i>	0.25
minimum N cell-quota	<i>QminN</i>	0.24
Phytoplankton threshold for grazing, is multiplied by VOLcell	<i>Athresh</i>	0.22
half-saturation constant for P	<i>Kp</i>	0.2
P-uptake rate measured at umax	<i>vmaxP</i>	0.14
phytoplankton volume/cell	<i>volcell</i>	0.1
half-saturation constant for N	<i>Kn</i>	0.02
minimum P cell-quota	<i>QminP</i>	$4.37 \times 10^{-3}$
<b>Zooplankton</b>		
maximum growth rate of zooplankton	<i>Zumax</i>	1.01
half saturation coefficient for grazing	<i>ZKa</i>	0.88
assimilation efficiency as a fraction of ingestion	<i>Zeffic</i>	0.58
zooplankton nitrogen/individual	<i>ZQn</i>	0.54
Zooplankton mortality constant for quadratic mortality	<i>Zm</i>	0.41
Zooplankton growth-dependent respiration factor	<i>Zrespg</i>	0.17
Zooplankton biomass-dependent respiration factor	<i>Zrespb</i>	0.13
proportion of grazed phytoplankton lost to sloppy feeding	<i>Zslop</i>	0.12
zooplankton carbon/individual	<i>ZQc</i>	0.04
zooplankton phosphorus/individual	<i>ZQp</i>	$1.69 \times 10^{-3}$
<b>Organic Matter</b>		
turnover rate for OM2A and OM2Z	<i>KG2</i>	0.94
decay rate of CDOM, 1/day	<i>KGcdom</i>	0.1
half-saturation concentration for O2 utilization	<i>KO2</i>	0.04
turnover rate for OM1A and OM1Z	<i>KG1</i>	0.04
O2 concentration that inhibits denitrification	<i>KstarO2</i>	0.03
half-saturation concentration for NO3 used in denitrification	<i>KNO3</i>	$3.16 \times 10^{-3}$
maximum rate of nitrification per day	<i>nitmax</i>	$8.44 \times 10^{-5}$
NH4 rate constant for nitrification	<i>KNH4</i>	$7.41 \times 10^{-5}$

Table S7: Sensitivity of phosphate to perturbations of individual parameters. Sensitivities are based on a 50% increase from the initial parameter value, where  $L1$  summarizes differences in model output from the default (see eq. (2)). Parameters that did not affect phosphate are not shown. Parameters are grouped by categories as optics, temperature, phytoplankton, zooplankton, and organic matter. <sup>tab:po4sens</sup>

Description	Parameter	L1
<b>Optics</b>		
Chla specific absorption at 490 nm	<i>astar490</i>	$9.01 \times 10^{-3}$
OMZ specific absorption at 490 nm	<i>astarOMZ</i>	$5.21 \times 10^{-4}$
OMA specific absorption at 490 nm	<i>astarOMA</i>	$5.13 \times 10^{-4}$
<b>Temperature</b>		
Optimum temperature for growth(C)	<i>Tref(nospA+nospZ)<sub>p1</sub></i>	0.16
